Lab 5: Post-hoc Tests & Factorial ANONA

PSC 103B

Marwin Carmo

Today's dataset

- We'll be using a modified version of last week's data set.
- I randomly chose 68 penguins from each species, because the manual post-hoc test we are doing requires equal group sizes.

```
1 penguins_data <- read.csv("data/penguins_103b.csv")</pre>
```

<u></u>

Post-Hoc Tests

different species of penguins had, on average, equal bill lengths, or whether there The one-way ANOVA we conducted last week we were interested in whether the was some difference in the average bill length among the 3 species.

```
my_anova <- aov(bill_length_mm ~ species, data = penguins_data)
                                                                                                                                                                                               Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 '
                                                                           Df Sum Sq Mean Sq F value Pr(>F)

                                                                                                                                           Residuals
                                                                                                           species
```

<u></u>

What can we conclude?

Post-Hoc Tests

- After a significant ANOVA result, we're interested in learning where those differences are.
- that your chances of a Type 1 error (saying 2 groups have different means when Post-hoc tests are meant to correct for the many comparisons you are doing, so they actually have the same means) stays at .05.
- There are multiple post-hoc tests available, and they differ in how conservative they are. We're focus on Tukey's Honest Significant Difference (HSD) Test.

Tukey's HSD

• It computes a value called a "Critical Difference", and so any group differences that are larger than the Critical Difference (CD) in absolute value are significant.

$$CD=q imes\sqrt{rac{MS_w}{n}}$$

ullet where n is the group size within each group, and MS_w is the Mean Squared Within you can get from your ANOVA table.

Find n and MS_w

u

```
<u></u>
  table (penguins_data$species)
                                      Gentoo
                                     Adelie Chinstrap
                                                                           1 n <- 68
```

MS_w (tip: look in the ANOVA summary)

```
<u></u>
                                                                                                                         0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1
                                          241.8 <2e-16 ***
                          Df Sum Sq Mean Sq F value Pr(>F)
2 4436 2217.9 241.8 <2e-16
201 1844 9.2
 1 summary (my_anova)
                                                             201
                                                                                               Signif. codes:
                                                                                                                           1 MSW <-
                                                             Residuals
                                           species
```

To find q, we can use the function $\mathsf{qtukey}()$, that takes 3 main arguments:

- p, which is the probability to the left of the critical value,
- nmeans, which is the number of groups we're comparing and,
- df, which is just df within
- If our test is conducted at the .05 level, then the probability below the critical value is .95.

Exercise

Find q using the qtukey() function. Set the values for the arguments p, nmeans, and df. Save your result to an object called qvalue. Tip: you can also find df within in the ANOVA summary

Find q

[1] 3.339252

UCDAVIS

Tukey's HSD

Now, we can go ahead and calculate our CD.

```
<u></u>
 sqrt (MSW / n)
  cd <- qvalue *
                                      [1] 1.228255
```

How can we get all the groups' means?

```
penguin_means <- tapply(penguins_data$bill_length_mm,
                     penguins_data$species,
                                          mean, na.rm = TRUE)
                                                                                          Gentoo
                                                                                                            47.60588
                                                                                                            38.38529 48.83382
                                                                                        Adelie Chinstrap
                                                              penguin means
```

UCDAVIS

Exercise

Find all the possible mean differences between groups and compare to the critical difference we just calculated. What can we conclude about those differences?

| <pre>1 adelie_mean <- penguin_means[1] 2 chinstrap_mean <- penguin_means[2] 3 gentoo_mean <- penguin_means[3]</pre> | |
|--|-----|
| 1 adelie_mean - chinstrap_mean | |
| Adelie -10.44853 | |
| 1 adelie_mean - gentoo_mean | (i) |
| Adelie -9.220588 | |
| 1 chinstrap_mean - gentoo_mean | [|

Chinstrap 1.227941

Tukey's HSD

| Comparison | Mean difference |
|--------------------|-----------------|
| Adelie - Chinstrap | -10.45 |
| Adelie - Gentoo | -9.22 |
| Chinstrap - Gentoo | 1.23 |

- Given our CD of 1.21 which of these differences are significant?
- We can say that Adelie has a significantly lower average bill length than both Chinstrap and Gentoo.
- And Chinstrap has a significantly longer bill length, on average, than Gentoo.

Tukey's HSD

R has a built-in function for Tukey's HSD, called TukeyHSD(), and the only argument you need to give it is the ANOVA object you saved earlier: 0

```
Fit: aov(formula = bill length_mm ~ species, data = penguins_data)
                                                                                                                                                                                                                                                                       9.222071 11.674988263 0.0000000
                                                                                                                                                                                                                                                                                                      7.994129 10.447047086 0.0000000
                                                                                                                                                                                                                                                                                                                                     0.0496478
                                                                                                                                                                                                                                                                                                                                     -2.454400 -0.001482326

UCDAVIS

Factorial ANOVA allow us examine in one test:

- is there an effect of Grouping Variable 1 (at least one mean is different in those groups)?
- is there an effect of Grouping Variable 2?
- is there an interaction between the 2 variables (so that the effect of Grouping Variable 1 depends on Grouping Variable 2, or vice versa)?

- levels of one factor, regardless of the other factors. Imagine studying how exercise and diet affect weight loss. If people lose more weight with exercise regardless of Main effect: When the average outcome changes consistently across different their diet, that's a main effect of exercise.
- another factor. Back to the exercise and diet example, if exercise leads to more • Interaction: When the effect of one factor changes depending on the level of weight loss only for people on a specific diet, there's an interaction.

- Let's assume we were interested in whether body mass differed not only among the 3 penguin species, but also whether it differed among males and females.
- If we were to do this as 2 separate ANOVAs, we would have 2 sets of hypotheses:
- One for the species of penguin:
- ullet $H_0:\mu_{Adelie}=\mu_{Chinstrap}=\mu_{Gentoo}$ (there is no difference in average body mass among the species).
- ullet H_A : At least one mean is significantly different from the rest.

- One for the sex:
- $lacktriangleq H_0: \mu_{female} = \mu_{male}$ (there is no difference in average body mass among male and female penguins).
- ullet $H_A:\mu_{female}
 eq\mu_{male}$ (note that because there are only 2 groups, we can be more specific with our alternative hypothesis).
- And we also have a hypothesis for the interaction:
- lacktriangle H_0 : There is no interaction between the species of penguin and their sex.
- lacktriangle H_A : There is an interaction between the species of penguin and their sex.

 In R where we "multiply" our two predictors to include an interaction between them.

```
0
      ~ species * sex, data = penguins_data)
                                                                                                                                                                                                                       Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' 1

<u></u>

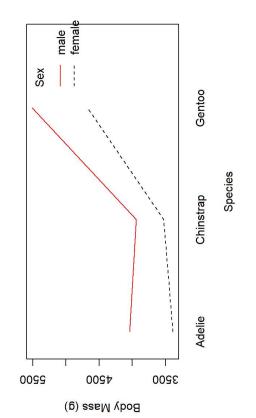

Interaction

- The difference in body mass between male and female penguins depends on the species.
- We can try to uncover what that interaction is by graphing the means.
- In this graph, we would have one grouping variable on the x-axis and the other grouping variable as different lines on the graph.
- To do this, we will use the function interaction.plot().
